Abstract. Structural performance deterioration of reinforced concrete structures has been extensively investigated, but very limited studies have been carried out to investigate the effect of reinforcement corrosion on time-dependent reliability with consideration of the influence of mechanical characteristics of the bond interface due to corrosion. This paper deals with how corrosion in reinforcement creates different types of defects in concrete structure and how they are responsible for the structural capacity deterioration of corrosion affected reinforced concrete structures during their service life. Cracking in cover concrete due to reinforcement corrosion is investigated by using rebar-concrete model and realistic concrete properties. The flexural strength deterioration is analytically predicted on the basis of bond strength evolution due to reinforcement corrosion, which is examined by the experimental data available. The time–dependent reliability analysis is undertaken to calculate the life time structural reliability of corrosion damaged concrete structures by stochastic deterioration modelling of reinforced concrete. The results from the numerical example show that the proposed approach is capable of evaluating the damage caused by reinforcement corrosion and also predicting the structural reliability of concrete structures during their lifecycle.

1. Introduction
Deterioration of reinforced concrete (RC) structures due to reinforcement corrosion is a growing problem worldwide. It typically involves cracking and spalling of concrete cover and reduction in area of steel reinforcement and loss of bond between concrete and corroded steel. This eventually affects the service life of the concrete structures and also increases the resources required for the maintenance and rehabilitation over time [1-5]. Managing corrosion damaged RC structure has become a great challenge both financially and technically. RC structures damaged by reinforcement corrosion compromises structural safety and durability by affecting their performance. The cost associated with managing these corrosion damaged RC structure (repair, rehabilitation, demolition) is in billion dollars [6-9]. For optimum and cost effective infrastructure management, time-dependent reliability analysis is considered as the effective tool. In time-dependent reliability analysis of deteriorating RC structures, the quantification of the damage caused by reinforcement corrosion is essential. Among these types of damage, only cracking in the concrete cover is visible and can be measured without affecting the functionality of the RC structures in operation.

Cracking in concrete cover is an important parameter which helps in condition monitoring of the RC structures. It is necessary to predict the internal damages such as residual strength deterioration...
from the observable surface condition during the routine inspection or maintenance process. Therefore, it is always beneficial to establish a prediction method to quantitatively assess the structural performance by assessing cracking in the concrete cover. In order to evaluate the residual strength of corroded RC structures, considerable investigations have been undertaken in the past two decades, mainly focusing on the relationship between rebar mass loss and residual strength [1-4]. However, limited research has focused on the relationship between cracking in the concrete cover surface and residual strength and its effect on the structural reliability of these corrosion damaged RC structures.

This paper presents a time-dependent reliability analysis of corrosion affected RC structures. At first, the evaluation of the damages caused by reinforcement corrosion such as rebar mass loss, cracking in concrete cover and residual strength loss is presented analytically. Then, a stochastic deterioration model based on a gamma process is adopted to assess the structural reliability. The results from the numerical example show that the proposed approach is capable of evaluating the damage caused by reinforcement corrosion and the structural reliability of corroded RC structures.

2. Damages caused by reinforcement corrosion
The progress of corrosion directly affects the performance and hence the remaining service life of a corroding RC structure [7]. The quantitative description of these damages associated with performance deterioration of corrosion damaged RC structures is the first step in structural reliability analysis of these structures. Therefore, in this section quantitative assessment of the damages caused by reinforcement corrosion is discussed.

2.1. Corrosion induced cover cracking
The corrosion products formed during corrosion process are expansive in nature, which causes two to six times volume increase as compared with the original steel [10]. The increase of volume per unit length due to bar corrosion $V$ can be obtained from the volume of rust minus the volume of the original rebar of a diameter $R_b$ consumed. This increment of volume per unit length of rebar creates a radial displacement at the rebar-concrete interface $u_{bx}$ which can be estimated from

$$u_{bx} = \frac{V}{2R_b} = \frac{1}{2} (\varepsilon_{vol} \cdot 1) R_b X_p$$

(1)

where $X_p$ is the corrosion level defined by the ratio of the mass loss of the corroded rebar to the original mass of the rebar and $\varepsilon_{vol}$ is the volume ratio of the corrosion product formed to its parent metal lies between 1.8 to 6.4 [10]. In this paper corrosion has been considered as uniform, therefore, reduction in rebar radius from the initial state $R_b$ when uniform attack penetration $x$ occurs can be evaluated from $R_{bx} = R_b - x$. The evolution of cracks in concrete cover is discussed in the analytical investigations by Chen and Alani [6], where the equivalent cracks width over the time was defined as the cumulated crack width over the cover surface. The intact cover concrete is treated as elastic material and the cracked concrete is considered as anisotropic in nature [6, 11]. From the anisotropic property and the bilinear softening law of the cracked concrete, normalized cumulative crack width over the concrete cover surface is obtained by considering boundary conditions and by ignoring the Poisson’s effect associated with the hoop strain of the completely cracked concrete, expressed here as

$$W_{cx} = \frac{E f_t u_{bx} \cdot a [R_y + R_c (l_o \cdot R_c) (l_o \cdot R_y) \cdot (R_c \cdot R_y)]}{b (l_o \cdot R_y) [1 \cdot R_c (l_o \cdot R_c) \cdot (R_c \cdot R_y)]}$$

(2)
where \( l_o \) is the material constant given by \( l_o = n_c l_{ch} / 2 \cdot b \) in which \( n_c \) is the number of cracks taken as 3 or 4 for the concrete around the rebar and \( l_{ch} \) is the characteristic length defined as \( l_{ch} = E \gamma / f_t^2 \) by Hillerborg et al. [12]; and \( \bullet (R_x, R_b) \) is the crack factor associated with the material properties and radial distance \( r \) between rebar surface \( R_b \) and concrete cover surface \( R_c \), defined as.

\[
\bullet(R_x, R_b) = \frac{R_x \cdot R_b}{l_o(l_o \cdot R_c)(l_o \cdot R_b)} + \frac{1}{l_o^2} \ln \frac{R_x}{R_b} \left| \frac{l_o \cdot R_b}{l_o \cdot R_c} \right|
\]  \( \text{(3)} \)

2.2. Residual strength deterioration

The flexural strength deterioration due to reinforcement corrosion was investigated by Nepal and Chen [7], where the analytical method was proposed to evaluate the residual strength of RC beam with corroded reinforcement by considering different failure modes of concrete and steel. In case of un-corroded perfectly bonded RC beam the strain compatibility condition exists, as given by design codes. Therefore, the initial flexural resistance of RC beams can be evaluated by using design codes. For the corroded RC beam when ultimate bond strength is insufficient to prevent anchorage failure, the tensile force generated in the corroded tensile steel can be obtained from

\[
f_{tx} = 2 n_b \bullet R_{bx} l_d T_{abx}
\]  \( \text{(4)} \)

where \( n_b \) is the number of the bottom tensile steel and \( l_d \) is the development length which can be evaluated from design code. \( T_{abx} \) is the ultimate bond strength of corroded rebar and is obtained from Nepal and Chen [9]. The strain compatibility of a RC beam with corroded reinforcement can be considered between un-bonded and bonded condition [13]. Assuming the deformation of concrete is mainly due to plastic deformation occurring within the plastic equivalent region, new strain compatibility of the corroded beam can be expressed as

\[
\bullet_{ax} = g_x \frac{d_x \cdot Y_x}{Y_x} \quad \bullet_{cx} = g_x \frac{Y_x \cdot d_x'}{Y_x}
\]  \( \text{(5)} \)

where the plastic equivalent region is defined as \( I_{eq} = 9.3 Y_x \) [14]. Parameters in equation (5) are defined as: \( \bullet_{cx} \) is ultimate strain of concrete; \( \bullet_{ax} \) and \( \bullet_{cx} \) are strains of tensile steel and compression steel, respectively; \( Y_x \) is the neutral axis depth from the edge of compression zone; \( d_x \) is the effective depth of beam and \( d_x' \) is the distance from the centroid of the compression steel to edge of the compressive fibre corresponding to corrosion level \( X_p \); and \( g_x \) is the interpolation factor which can be obtained by considering the bond strength value of perfectly bonded and un-bonded condition of the RC beam. By utilizing the concept given by Cairns and Zhao [15] that the corroded RC beam still follows the condition of equilibrium of resultant tensile and compressive forces acting at the beam section, the residual flexural strength can be evaluated by

\[
M_{ax} = f_{cxx} \left( d_x \cdot 0.4 Y_x \right) + f_{scx} \left( d_x \cdot d_x' \right)
\]  \( \text{(6)} \)

where \( f_{cxx} \) and \( f_{scx} \) are the compressive forces acting at the centroid of compression zone and the centroid of the compressive steel of the corroded beam, respectively.
2.3. Structural reliability analysis

The gamma process has been often adopted for structural deterioration modelling [6, 16, 17]. The gamma process is a stochastic process with independent non-negative increments having a gamma distribution with a given average of deterioration rate. Structural resistance degradation caused by reinforcement corrosion is a continuous and non-negative phenomenon [5, 7]. Therefore, the gamma process is suitable for the stochastic modelling of structural resistance deterioration in corrosion affected RC structures during their lifecycle. In this gamma process deterioration model, cumulative resistance deterioration \( J \) is considered as a random quantity with the gamma distribution, and has the shape parameter \( \cdot_x > 0 \) and scale parameter \( \cdot > 0 \). Then, the probability density function of this random quantity \( J \), i.e. the structural resistance during the lifecycle at time \( t \) and corrosion level \( X_p \) \((X_p > 0)\), can be formulated as

\[
 f_{J_X}(J) = \text{Ga} \left( J; \cdot_x, \cdot \right) = \begin{cases} \cdot_x \cdot_x x e^{-x J \cdot_x}, & \text{for } J > 0 \\ 0, & \text{elsewhere} \end{cases}
\]

where \( \cdot_x = \int_0^\infty y^{-x+1} e^{-y} dy \) is the gamma function for shape parameter \( \cdot_x > 0 \). The scale parameter \( \cdot \) could be estimated from statistical estimation methods such as a Maximum Likelihood Method by maximizing the logarithm of the likelihood function of the increment of the parameter [17] and the shape function \( \cdot_x \) can be obtained from \( \cdot_x = \cdot J_x \) in which \( J_x \) indicates the average deterioration rate associated with the reinforcement corrosion such as flexural strength deterioration in ultimate limit state. Assuming \( J_L \) as the maximum allowable limit of the structural deterioration, from the definition of probability of failure and by integrating probability density function given in equation (7), the structural reliability associated with structural resistance deterioration is given by

\[
 R(t) = I \cdot F(t) = I \cdot P_r \left[J_x \cdot J_L \right] = I \cdot \int_{J_L}^\infty f_{J_X}(J) dJ = \frac{\cdot_x \cdot_x \cdot} {\cdot_x} \left[ \cdot \right] \qquad (8)
\]

where \( \cdot = \int_{-\infty}^z y^{-x+1} e^{-y} dy \) is the incomplete gamma function for \( z > 0 \) and \( \cdot > 0 \).

3. Numerical example

A simply supported RC beam of 5m span of a bridge exposed to an aggressive environment as defined by Eurocode 2 is now utilised to demonstrate the applicability of the proposed method for assessing the structural performance and a time-dependent reliability analysis during its service life. The beam is doubly reinforced with the cross-sectional width \( b = 300 \text{ mm} \) and effective depth \( d = 560 \text{ mm} \) Four steel rebar with diameter \( D_b = 20 \text{ mm} \) are provided as the tensile reinforcement and two rebar of diameter \( D_{bc} = 16 \text{ mm} \) are provided as the compressive steel with clear cover thickness \( C = 40 \text{ mm} \) along with the stirrup of diameter \( D_{st} = 6 \text{ mm} \) at spacing of 100 mm. The concrete has a characteristic compressive strength \( f_{ck} = 40 \text{ MPa} \), the yield strength of original reinforcing steel \( f_{yk} = 460 \text{ MPa} \) with
modulus of elasticity $E_s = 200$ GPa. The characteristic compressive strength of concrete is used for estimating other relevant properties of concrete i.e. tensile strength $f_t = 4.6$ MPa; modulus of elasticity $E_c = 37$ MPa [18, 19]. The concrete fracture energy $G_F = 200$ N/m is adopted and ultimate cohesive crack width $w_c = 1.48$ mm and critical crack width $w_{cr} = 0.23$ mm are estimated from CEB-FIP [19] for given compressive strength and assumed maximum aggregate size of 20 mm. The total number of crack $n_c = 4$ is adopted here. The concrete creep coefficient $\varepsilon_c = 2.0$ and Poisson’s ratio $\nu = 0.18$ and the volume ratio $\varphi_{vol}$ of the corrosion products is taken as 2.0 [10]. The RC beam has minimum service life of 60 years and is operated in aggressive environments with mean annual corrosion current per unit length $i_{corr} = 1 \mu A/cm^2$.

The results in figure 1 show the predicted results of residual flexural strength as a function of corrosion level. The predicted results are then compared with previous experimental investigations obtained from various sources. In figure 1, the residual load capacity is represented by the normalised flexural capacity, which is calculated by dividing the flexural capacity of corroded element by the capacity of the non-corroded element. It is found that the trend of predicted flexural strength deterioration match well with the published experimental data available from various sources. At the initial stage, the flexural strength of the corroded element deteriorates slowly almost in linear trend. When corrosion level reaches about 5%, considerable deterioration occurs due to the reduction in bond strength and corresponding anchorage failure, which occurs before yielding of the steel and the surrounding concrete.

Structural damage assessment and performance predictions using monitored data is critical to determine cost-effective infrastructure management strategies [20,21]. During the routine inspections of concrete bridges, cracking in concrete cover is the most important information recorded for condition rating. Based on the condition ratings collected during inspections, Bridge Management Systems (BMSs) are developed for optimum allocation of limited resources available [22]. Depending on the size of the cracks, these defects in concrete cover due to corrosion can be classified in different categories such as spalling; minor and major cracking etc. The defects in concrete and corresponding rebar loss are described in figure 2. Here the hair line crack is represented by crack $<0.05$ mm; minor cracking $0.05-0.1$ mm; major cracking $0.1-0.4$ mm and spalling $0.4-1.0$ mm. When hair line crack appears at the concrete cover there is about 2% loss in rebar and as the crack size progress the reduction in rebar continuously increases, reaching approximately 13% when the spalling of the concrete cover takes place.
Influence of different types of aforementioned defects in concrete cover on the structural behaviour of corroded RC structure is presented in figure 3. From the results, till minor cracking in the concrete cover there is no significance change in residual flexural strength. As the defects reach to spalling stage, flexural strength decreases significantly. This clearly shows that, defects in concrete cover have significant effect on residual strength of corroded RC structures. In comparing these results of residual strength, the reduction in residual strength in unconfined concrete is relatively higher than in confined concrete. For instance when the defect in the concrete cover is spalling, the residual flexural strength of the confined element maintains about 60% of its initial strength, whereas in unconfined element it only maintains 40% of its initial strength. This is due to the absence of transverse reinforcement (stirrups) in unconfined concrete. Hence, the results from figure 3 and figure 4 show that, at the same stage of defects in the concrete cover, unconfined concrete is more susceptible than confined concrete.

The structural reliability of confined and unconfined concrete in terms of flexural strength deterioration is given in figure 4. Here, different allowable flexural strength deterioration limits, i.e. $J_L = 20\%$; 25% and 30%, respectively, have been considered during the analysis. Here again, at any stage of cover cracking structural reliability continuously decreases for both unconfined and confined concrete, showing higher probability of failure for a lower allowable deterioration limit. Furthermore from the time-dependent reliability analysis shown in figure 4, it is clear that the unconfined concrete
has considerably lower structural reliability than the confined concrete when the same predefined allowable limit and concrete cover crack width are considered.

![Figure 4. Structural reliability versus surface crack width for various allowable flexural strength deterioration limits of unconfined and confined concrete.]

4. Conclusions
This paper presents a new approach for evaluating the damages caused by reinforcement corrosion together with its effect on structural reliability. On the basis of the results obtained from the numerical example, following conclusions are drawn: a) The proposed approach is capable of evaluating structural behaviour and defects of corrosion damaged RC structures; b) Flexural strength decreases significantly after 5% mass loss due to significant reduction in bond strength loss; c) Further progress of corrosion causes significant reduction in rebar size which in turn widens the crack in concrete cover, and consequently reduces residual strength of bond and flexural strength; d) The reliability of the corroded structure decreases with progress of defects in concrete. Further investigations are required to include the effect of external loading on the performance of corroded RC structure serving in aggressive environment.
